**Abstract**

The paper deals with the identifying the cultural characters of Brown leaf spot of rice caused by *Helminthosporium oryzae* (Syn: *Bipolaris oryzae*) pathogen and identifying the most virulent isolate. Five isolates are collected from various places and identified isolates of *H. oryzae* were designated as Ho₁ (Puthoor), Ho₂ (Kathiramangalam), Ho₃ (Annamalainagar), Ho₄ (Keerapalayam) and Ho₅ (Kodipallam). All the five isolates of *H. oryzae* (Ho₁, Ho₂, Ho₃, Ho₄ and Ho₅) exhibited difference in the morphological characters such as colony characters, length and width of the conidium, colour of the conidia etc., Among the five isolates of *H. oryzae*, the isolate (Ho₁) collected from Puthoor village was found to be more virulent recording maximum brown spot incidence. The isolate Ho₅ collected from Kodipallam village was the least virulent.

**Key words**: Spore colony characters, Pathogenicity studies, Brown leaf spot of rice

**Introduction**

Rice (*Oryza sativa* L.) is the second most cultivated crop worldwide and it has been estimated that half the world’s population survives wholly or partially on this crop (Van Nguyen and Ferrero, 2006) and rice provides more calories per ha than any other cereal food grains. Also, rice crop has been under cultivation from time immemorial, being grown under varying climatic conditions in different parts of the world. Rice crop is widely affected by a number of diseases caused by fungi, bacteria, viruses and mycoplasma which results in considerable yield losses (Ou, 1985). Among the various fungal diseases of rice, brown spot or sesame leaf spot incited by *Helminthosporium oryzae* (Breda de Haan) Subram. and Jain (Syn: *Bipolaris oryzae* (Breda de Haan) Shoemaker) is found to occur in most rice growing areas. The disease is also referred as fungal blight or Helminthosporiose. In India, the first occurrence of the disease was perhaps during 1918-1919 in the deltac tracts of Godavari and Krishna (Sundaraman, 1922). The major objectives of this paper are identifying the cultural characters of pathogen and identifying the most virulent isolate.

**Materials and Methods**

**Isolation and maintenance of culture (in vitro)**

The pathogen *H. oryzae* was isolated from brown spot infected leaves of rice collected from the villages which showed the maximum brown spot disease incidence in each region by the tissue segment method (Rangaswami, 1972). The affected leaf portions were cut into small bits, surface sterilized with 0.1 per cent mercuric chloride solution for one min., washed using sterile dist. water and then placed on special medium viz., Rice Polish Agar Medium (Gangopadhyay, 1984) and incubated at room temp. (28 ± 3°C) for seven days. The fungus was subsequenly purified by single spore isolation and the culture was maintained both on Czapek’s (Dox) Agar and Potato Dextrose Agar slants for further studies. Slants were examined periodically for purity, viability and pathogenicity of *H. oryzae*.

**Cultural Characteristics of the Isolates**

Fifteen ml of the sterilized PDA medium was poured into sterile Petri dishes and allowed to solidify. A nine mm culture disc from each isolate of *H. oryzae* was aseptically placed on the medium and incubated at room temperature for seven days under room temperature (28±2°C). After incubation the mycelial growth, colour and spore characters were assessed and recorded. Micrometric measurements of conidia was done after staining with lactophenol cotton blue and observed under microscope. The identified isolates of *H. oryzae* were designated as Ho₁ (Puthoor), Ho₂ (Kathiramangalam), Ho₃ (Annamalainagar), Ho₄ (Keerapalayam) and Ho₅ (Kodipallam).

**Pathogenicity Studies**

The pathogenicity of the fungus was tested on ADT 36 rice variety raised for this purpose in pots.
Spore suspensions with adequate cfu viz., 50,000 spores/ml were prepared in two per cent sucrose solution and the plants were sprayed with an atomizer. The inoculated seedlings/pots were maintained in polyhouse with frequent sprinkling of water to maintain high humidity to favor conditions for infection. Development of characteristic symptoms of brown spot was assessed and the pathogen was reisolated from the infected leaves and compared with the original culture in special medium. The isolate collected from Annamalai nagar proved as the most virulent isolate as it registered the maximum Per cent Disease Incidence in the pathogenicity studies.

Results and Discussion

Morphological Characters of *H. Oryzae*

In the present study, from each region the villages which showed the maximum disease incidence were chosen for the isolation of the pathogen. Thus, five isolates of *Helminthosporium* sp. were isolated, identified and designated as Ho1, Ho2, Ho3, Ho4 and Ho5 (Table 2).

The colony characters of the isolates (Ho1, Ho2, Ho3 and Ho5) were observed visually and results are presented in table 1. Colony morphology of all the isolates showed olivaceous, light brown to black, septate, profuse aerial/submerged and branched mycelium. The colour of the conidia was brown to light brown colour. The conidia were slightly curved with a bulge in the middle and tapering towards the ends and when fully mature they were brownish in colour.

The size of the conidia significantly varied among the isolates from 29.3 to 33.2 µm length and 13.5 to 14.8 µm width. The maximum conidial length was observed in Ho1 followed by Ho3, Ho8, Ho4 and Ho2 in the decreasing order of merit. The maximum conidial width was observed in Ho3 followed by Ho8, Ho1, Ho2 and Ho5 in the decreasing order of merit. The number of septations ranged from 3 to 5 and maximum was observed in Ho4.

The colony morphology of all the isolates showed olivaceous, light brown to black, septate, profuse aerial/submerged and branched mycelium. The colour of the conidia was brown to light brown colour. Sakamoto (1934) noticed that *H. oryzae* had branched mycelium and septate conidia with variations in size. A similar observation was made in the present study with reference to the mycelium and conidia of Ho3 isolate. The isolates of *H. oryzae* causing brown spot of rice were divided into several groups based on morphological and cultural characters (Vijayakumar, 1998).

In the present study, the size of the conidia significantly varied among the isolates from 29.3 to 33.2 µm length and 13.5 to 14.8 µm width with septations ranging from 3 to 5. Similar to the present observations the variation in length and breath with individual isolates was reported by earlier investigators (Unnikrishna Pillai, 1988; Vidhyasekaran et al., 1991; Prasad and Bharat, 1995; Harish et al., 2007). These earlier reports lend support to the present findings.

Pathogenicity of *H. oryzae* Native Isolates

The data depicted in table 2 revealed varied levels of pathogenicity with different isolates. Among the five isolates of *H. oryzae* collected from different conventionally rice growing areas, the isolate Ho1 collected from Puthoor village of Kollidam region was found to be more virulent recording maximum disease incidence of 67.56 per cent (75DAT) followed by Ho2 (58.20 %) collected from Annamalainagar village. The isolates Ho2 and Ho5 showed 44.00 and 43.92 per cent disease incidence and they were on par with either other. The isolates Ho1 and Ho5 recorded 43.50 and 38.85 per cent disease incidence at 45 DAT itself. The most virulent isolate of *H. oryzae* (Ho1- Puthoor) was identified in this study.

The variability in the pathogenicity among the isolates of *H.oryzae* was reported by several workers (Lee et al., 1984; Prasad and Bharat, 1995; Harish et al., 2007; Peeyush Kumar et al., 2011). The variations in brown spot incidence in different locations could well be attributed to the difference in virulence of the *H. oryzae* isolates. Harish et al. (2007) mentioned that among the fifteen isolates collected from various areas of Tamil Nadu, the isolate collected from Ammapettai, Thanjavur district recorded maximum (82.96 %) brown spot disease index in ADT 36 variety. Vijayakumar, (1998) also mentioned that variability in virulence among the five isolates *H. oryzae* on rice. In the present study, the disease incidence was the maximum in 75 DAT plants. A similar observation was made by Misra (1973) with regard to *H. oryzae* infection in rice. The susceptibility of rice plant to the disease at the later stages of growth might be due to the decline in the *in situ* defense mechanism. The above reports are in agreement with the present investigation.
